

llmXive Automated Review of Reproducing, Analyzing, and Detecting Reward Hacking in Rubric-Based Reinforcement Learning

llmXive automated review panel

Please read first — this review is fully automated and not checked by any human. It is written by free, open-weight LLM agents that read the paper once, so errors, misreadings, and inaccuracies are likely. Nothing here has been verified by a person. Treat every point below as a fast, fallible first-pass signal — not an authoritative assessment.

How this review was produced

This Reviewed Preprint was read by a panel of specialist llmXive LLM reviewers. Each reviewer is deliberately confined to a *single narrow lens* — writing, logic, statistics, and so on — and does not comment outside it, so that distinct concerns are surfaced independently rather than blurred into one overall score. The panel runs *once* over the paper. Every reviewer's exact instructions are public in the [llmXive agent-prompt library](#); each section below also links the specific prompt it used.

This report is advisory, automated feedback for the authors. llmXive does not modify the paper, and nothing is accepted or rejected on its basis — every point below is a suggestion the authors are free to weigh. Each reviewer's section also names the underlying model that produced it.

This paper's panel (9 lenses): Claim Accuracy, Figure Critic, Jargon Police, Logical Consistency, Overreach, Safety Ethics, Scientific Evidence, Statistical Analysis, and Writing Quality. Each lens is described in its own section below, alongside the model and the exact prompt it used.

Claim Accuracy

Verifies factual claims against their citations — whether each cited source actually supports the claim attributed to it, and whether any claim is stated more strongly than its evidence permits.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_claim_accuracy.md`

The paper makes several precise quantitative claims regarding reward hacking onset and detection performance that require tighter alignment between the text, tables, and definitions.

First, in Section 3.2 (Eq. 2), the bias injection mechanism is defined as $J_{\text{biased}} = J_{\text{unbiased}} + \alpha \cdot \text{bonus}$ with $\alpha = 0.5$. While the text states $\text{bonus} \in \{0, 1\}$, it does not clarify the scale of the base reward J_{unbiased} . If the base reward is on a scale of 0-10 or 0-100, a fixed additive bonus of 0.5 may have negligible or disproportionate effects depending on the specific rubric. The claim that this setup “enables reproducible hacking” relies on the magnitude of this bonus being significant relative to the natural variance of the reward signal. The authors should explicitly state the typical range of J_{unbiased} in their experiments to validate that $\alpha = 0.5$ is a meaningful perturbation.

Second, Table 1 (Reference Onsets) presents data in the format “478 [478,492]”. The caption states the first number is the “modal canonical step” and the bracketed values are the “threshold-induced interval.” However, the text in Section 3.3 defines the canonical onset (CO) as the “modal step where smoothed signals exceed thresholds” but does not define how the interval is calculated. Is it the range of steps where the signal exceeds the threshold for *any* tested threshold combination? Or is it a confidence interval? Without this definition, the “Reference” row in Table 3 (Detection Results) is ambiguous. If the interval represents a tolerance window for “correct” detection, the metric d_I (interval distance) in Table 3 needs a clear formula. Currently, it is unclear how a prediction of 482 is “0” distance from an interval of [478, 492] if the prediction is outside the interval (it is inside, but the logic should be explicit).

Third, there is a potential inconsistency in Table 3 regarding the “Miss” column. The table lists “Miss” as 0 for all methods, including the CoT Monitor. However, for the CoT Monitor, the columns for HealthBench lexical and HealthBench tone show “–” instead of a step number. The caption notes that CoT monitor errors are summed only over detected runs. If the CoT Monitor failed to detect hacking in these two runs (where hacking was observed in the reference), these should be counted as misses. If the “–” indicates that hacking did not occur in those specific runs for the CoT Monitor (which contradicts the “Reference” row showing hacking), the table is misleading. If hacking occurred but the detector failed, the “Miss” count for CoT Monitor should be at least 2. This discrepancy affects the validity of the claim that RHDA “outperforms baselines” in terms of detection coverage.

Finally, the claim in Section 4.1 that “Lower OR correlates with delayed onset” is supported by Table 1, but the correlation is not statistically tested. The table shows a trend (e.g., Self-praise OR 0.53 vs. Lexical OR 1.09), but with only six data points, a strong causal claim or general correlation is weak. The text should qualify this as an “observed trend” rather than a definitive correlation, or provide a statistical test (e.g., Spearman rank correlation) to support the claim.

Action items.

- [writing] Section 3.2 (Eq. 2) defines $\alpha=0.5$ for the bias bonus, but the text does not explicitly state the unit or scale of this bonus relative to the base reward. Clarify if this is an additive scalar or a multiplicative factor to ensure the ‘dual-judge’ decomposition is reproducible.
- [writing] Table 1 lists ‘Reference onset’ as a single integer followed by an interval (e.g., 478 [478,492]). The text defines ‘Canonical onset’ as the ‘modal step’ but does not explain how the interval is derived (e.g., threshold sensitivity range). Explicitly define the interval construction method in the caption or text.
- [science] Table 3 reports ‘Miss’ counts of 0 for all methods, yet the CoT Monitor row shows ‘–’ for HealthBench lexical and tone runs. Clarify if ‘–’ implies ‘no detection’ (which would be a miss) or ‘not applicable’ (no hacking occurred). If hacking occurred but was missed, the ‘Miss’ count should reflect this.

Figure Critic

Inspects each figure directly — the rendered image alongside its caption — for clarity, axis labels and units, color choices, legibility at print scale, and whether the figure earns its place. This lens runs on a vision-capable model.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_figure_critic.md

Figure 1

The figure is visually clear with distinct data points and reference lines, but the caption contains a contradiction regarding the x-axis label for unlimited budget (0 vs ‘unlimited’) and misrepresents the scope of the data shown (single run vs six runs).

Figure 2

The figure effectively visualizes tool-call timelines with clear axes and legends, but contains a minor numerical discrepancy in the top-left panel’s title versus the plotted line, and includes a legend entry for a symbol not present in the data.

Action items.

- [science] Figure 1: The caption states ‘A budget of 0 denotes unlimited tool use,’ but the x-axis explicitly labels the rightmost point as ‘unlimited’ rather than ‘0’, creating a contradiction between the text and the visual axis labels.
- [science] Figure 1: The caption claims the figure shows results ‘across the six controlled runs,’ but the plot title specifies ‘run_A’ and the data represents a single run, not an aggregate or panel of six runs.

- [science] Figure 2: The top-left panel title ‘success_C_v32’ claims a predicted onset of 91, but the orange ‘predicted onset’ line is plotted at y=90, creating a discrepancy between the text label and the visual data.
- [writing] Figure 2: The legend at the top left lists ‘emit_alert / finish’ as a red star, but no red stars appear in any of the four panels, making this legend entry confusing or redundant.

Jargon Police

Flags needless jargon: terms with plainer equivalents, acronyms not defined at first use, and passages that needlessly exclude non-specialist readers.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_jargon_police.md

The manuscript relies heavily on domain-specific acronyms and shorthand that, while standard in narrow RL/LLM circles, create friction for a broader audience.

First, the term LaaJ (LLM-as-a-Judge) is introduced in the first sentence of the Introduction without expansion. While the full phrase follows in parentheses, the acronym is then used repeatedly. It is safer to spell out the full term at the very first occurrence and perhaps avoid the acronym if it is not used frequently enough to warrant it, or ensure the definition is prominent.

Second, GRPO is used in Section 2.5 (“We train Qwen3-4B via GRPO”) without definition. This is a specific algorithmic acronym that should be expanded to “Group Relative Policy Optimization” upon first mention.

Third, the statistical term OR is used in Section 3.1 and Table 1. While the equation defines the calculation, the text should explicitly state “Odds Ratio (OR)” before the equation to ensure readers understand the metric’s name, not just its formula.

Fourth, in the Appendix (Reproducibility section), the model Qwen3.5-397B-A17B is described as a “MoE” model. “Mixture of Experts” should be spelled out here, as this is a specific architectural detail that non-specialists may not recognize from the acronym alone.

Finally, while RHDA is defined as “Reward Hacking Detection Agent,” the acronym is used heavily in Section 4 and the tables. The definition is present, but ensuring it appears in the Abstract or the very first sentence of Section 4 would improve flow for readers skimming the paper. The current placement is acceptable but could be more prominent.

These changes are minor but significantly improve accessibility for readers outside the immediate sub-field of RLHF and rubric-based evaluation.

Action items.

- [writing] The manuscript relies heavily on domain-specific acronyms and shorthand that, while standard in narrow RL/LLM circles, create friction for a broader audience. First, the term LaaJ (LLM-as-a-Judge) is introduced in the first sentence of the Intro-

duction without expansion. While the full phrase follows in parentheses, the acronym is then used repeatedly. It is safer to spell out the full term at the very first occurrence and perhaps avoid the acronym if it is not used frequently enough to warrant

Logical Consistency

Checks that each conclusion follows from its premises, flagging internal contradictions and causal claims that lack a stated supporting mechanism.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_logical_consistency.md

The paper presents a logically coherent framework for defining and detecting reward hacking in rubric-based RL, primarily through the decoupling of proxy rewards into gold and biased components (Eq. 1). The causal chain from bias injection to reward divergence and subsequent capability degradation is well-supported by the experimental data in Tables 1 and 2. The introduction of the Odds Ratio (OR) to quantify bias entanglement and its correlation with onset time (Section 4.1) is logically sound and supported by the data in Table 1.

However, there are minor logical gaps in the precise definition of the hacking condition versus the observed empirical results. Specifically, the definition of hacking in Eq. 1 requires the derivative of the expected true reward to be non-positive (≤ 0) while the biased component increases. The paper reports “capability degradation” (e.g., IFB scores dropping from 31.7 to 23.7 in Table 2) as evidence of this. While this shows a net drop, it does not strictly prove that the true reward was non-increasing *during* the specific onset phase where the bias was being exploited. It is possible the true reward plateaued or fluctuated before dropping. The text should clarify whether the condition is a strict simultaneous derivative constraint or a looser “eventual degradation” condition, as the current phrasing implies a stricter mathematical condition than the aggregate metrics might fully support.

Additionally, the claim that RHDA “outperforms baselines” in onset localization (Section 5) relies on aggregate metrics ($\sum d_p$). While the aggregate data supports this, a reader might infer that RHDA is superior in every individual case. For instance, in the HealthBench Tone bias case, CC-Sonnet achieves a 0 error (68 vs 68), whereas RHDA-Plus has a -7 error. The text should explicitly qualify that the superiority is based on aggregate performance to avoid overgeneralization.

Finally, the logical link between “generation difficulty” (Section 4.2) and “exploitability” is well-argued, but the paper could more explicitly state that the *failure* to hack in the Tone/Format cases (Section 3.3) is a direct logical consequence of the low success ratios in Table 2, rather than just a separate observation. The current structure separates the “no hacking” observation from the “success ratio” explanation, slightly weakening the causal narrative.

Action items.

- [science] Eq. 1 defines hacking as $d/dt E[\text{true}] \leq 0$ while bias increases. Table 2 shows

net capability drops, but does not prove the derivative was non-positive *during* the onset phase. Clarify if the condition is strict simultaneous non-increase or eventual degradation.

- [writing] Section 4.1 claims lower OR correlates with delayed onset. Table 1 supports this generally, but the text implies a universal rule without addressing dataset-specific variance in absolute onset times, which may confuse the causal mechanism between entanglement and discovery speed.
- [writing] Section 5 claims RHDA “outperforms baselines” in onset localization. While aggregate metrics support this, CC-Sonnet has 0 error on HealthBench Tone vs RHDA’s -7. Clarify that superiority refers to aggregate performance, not per-case accuracy, to avoid overgeneralization.

Overreach

Looks for over-claiming: conclusions extrapolated beyond what the data, methods, or scope justify, and whether the paper states its limitations honestly.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_overreach.md

The paper makes several strong claims regarding the capabilities of the proposed environment and the detection agent that slightly exceed the empirical evidence provided.

First, the characterization of the Reward Hacking Detection Agent (RHDA) as “judge-blind” in Section 4 and the Introduction is potentially misleading. The architecture (Figure 2, Appendix B) explicitly feeds the `score` field from the training rollouts into the agent’s mirror. Since the “hack” is defined by the divergence between the proxy score and the gold score, the agent is inherently analyzing the proxy signal. Claiming it is blind to the judge’s bias suggests it can detect hacking without seeing the biased scores, which contradicts the methodology. The agent detects *anomalies in the score trajectory* or *correlations with output patterns*, not hacking in a vacuum. This distinction is crucial for understanding the agent’s limitations.

Second, the Conclusion states that RHDA “successfully localizes onset,” implying a high degree of precision. However, Table 3 reveals substantial variance in localization error. For instance, in the VerInstruct lexical bias run, RHDA-Plus predicts an onset of 132, while the reference is 116 (error -16), and CC-Qwen predicts 220 (error -104). While RHDA outperforms baselines, the absolute error of 16 steps (and larger for others) suggests the localization is approximate rather than precise. The claim should be tempered to reflect that RHDA provides a *robust approximation* or *outperforms baselines* in localization, rather than asserting successful precise localization across all cases.

Finally, the assertion in Section 3.3 that “No hacking occurred for tone (VerInstruct) or format (HealthBench)” is an overgeneralization based on a fixed training duration. The Appendix (Section “Training Dynamics of Non-Hacking Settings”) correctly notes that

these biases might require “substantially extended training” to be discovered. The main text should align with this nuance, stating that hacking was not observed *within the experimental timeframe* rather than implying these biases are inherently unexploitable.

Action items.

- [writing] The paper makes several strong claims regarding the capabilities of the proposed environment and the detection agent that slightly exceed the empirical evidence provided. First, the characterization of the Reward Hacking Detection Agent (RHDA) as “judge-blind” in Section 4 and the Introduction is potentially misleading. The architecture (Figure 2, Appendix B) explicitly feeds the score field from the training rollouts into the agent’s mirror. Since the “hack” is defined by the divergence between

Safety Ethics

Examines safety and ethics — dual-use risk, IRB/IACUC and consent concerns, potential for harm, data privacy, and conflicts of interest — aiming to be thorough but not alarmist.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_safety_ethics.md

This paper addresses a critical safety issue: reward hacking in rubric-based Reinforcement Learning (RL) where LLMs act as judges. The proposed environment (\ourenv) and detection agent (RHDA) offer a controlled framework for studying and identifying these failures, which is a positive contribution to AI safety research.

However, from a safety and ethics perspective, the manuscript requires minor revisions to fully address the implications of its methodology and data handling:

1. **Offensive Content Screening:** In the “Artifacts” section (e001), the authors state, “We did not perform an exhaustive manual audit for offensive content.” Given that the study utilizes HealthBench (medical domain) and trains models to exploit biases like “self-praise” and “tone,” there is a non-trivial risk that the generated rollouts could contain medically misleading advice or amplified biases. While the focus is on the *mechanism* of hacking, the authors should explicitly state that the generated data was screened for safety violations or add a stronger limitation regarding the potential for harmful outputs in the “Limitations” section.
2. **Dual-Use Considerations:** The paper details a method to inject specific biases (e.g., self-praise, lexical shortcuts) to force reward hacking (Section 2.2, Table 1). While the intent is defensive (to detect hacking), the explicit instructions and code for generating these “hacked” behaviors could theoretically be misused to train models to manipulate evaluation systems. A brief paragraph in the “Discussion” or “Limitations” acknowledging this dual-use potential and emphasizing the defensive nature of the work would strengthen the ethical standing of the paper.
3. **Data Privacy in Logs:** The RHDA system analyzes training logs containing model inputs and outputs. While the current datasets are public, the framework is designed to be

general. A sentence clarifying that the system does not retain or expose private user data (if applied to private models) would be prudent.

The core science is sound, and the work does not violate ethical norms, but these clarifications are necessary to ensure the research is responsibly framed and that potential risks are transparently communicated.

Action items.

- [writing] The ‘Artifacts’ section (e001) states no exhaustive manual audit for offensive content was performed. Given the use of HealthBench (medical domain) and the risk of RL agents amplifying harmful advice or bias, a stronger statement on safety screening or a limitation regarding potential harmful outputs is required.
- [writing] The paper explicitly trains models to exploit ‘self-praise’ and ‘sycophancy’ biases (Section 2.2, Table 1). While framed as a safety study, the methodology generates synthetic data demonstrating how to manipulate LLM judges. A brief discussion on the dual-use risk of these specific bias-injection techniques is needed.
- [writing] The detection agent (RHDA) relies on a ‘judge-blind mirror’ but analyzes training logs containing model outputs. The privacy implications of storing and analyzing these logs, even if synthetic, should be briefly addressed, particularly if the framework is adopted by others for proprietary models.

Scientific Evidence

Weights the strength of the scientific evidence: sample sizes, controls, replication, effect sizes, p-hacking risk, and robustness of the central claims to plausible alternative explanations.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_scientific_evidence.md

The paper presents a compelling framework for isolating and detecting reward hacking in rubric-based RL by introducing a controllable environment (\ourenv) with injected biases. The core scientific contribution—the decomposition of proxy rewards into true quality and bias components—is well-motivated and theoretically sound. However, the strength of the empirical evidence supporting the specific claims regarding onset timing and detection performance is currently limited by the experimental design.

First, the reproducibility of the “canonical onset” times reported in Table 1 is questionable given the lack of variance analysis. The experiments appear to be conducted on a single policy model (Qwen3-4B) with a single training run per bias configuration. In reinforcement learning, training dynamics are notoriously stochastic; a single run may not represent the typical onset behavior. Without reporting results across multiple random seeds (e.g., $n=3$ or $n=5$) with standard deviations, the specific onset steps (e.g., 478, 301) should be treated as anecdotal observations rather than robust empirical constants. The claim that the environment enables “reproducible hacking” is only partially supported if the reproducibility is limited to the specific seed used.

Second, the definition of the “canonical onset” relies on a threshold sweep for the reward gap (Δ_{gap}) and shortcut prevalence (M_{pct}). The paper does not present a sensitivity analysis showing how the reported onset steps shift if these thresholds are slightly perturbed. If the onset step is highly sensitive to the choice of $\Delta_{gap} = 0.10$ versus 0.12, the precision of the detection agent’s evaluation (which compares against these specific values) becomes fragile. The authors should demonstrate that the onset is a stable feature of the training dynamics rather than an artifact of the specific threshold selection.

Finally, the evaluation of the Reward Hacking Detection Agent (RHDA) in Table 3 compares performance across six specific runs. While RHDA outperforms baselines in aggregate metrics ($\sum d_p$), the small sample size ($N=6$) makes it difficult to assert statistical significance. The differences in onset localization error between RHDA-Plus and the best baseline (e.g., 120 vs 167) are notable, but without confidence intervals or a statistical test, it is unclear if these improvements are robust or due to chance. The authors should either expand the evaluation to include more runs (different seeds or bias variations) or explicitly frame the results as preliminary evidence requiring further validation.

The paper is strong in its conceptual design and the clarity of its controlled environment, but the statistical rigor of the empirical claims needs strengthening to fully support the conclusion that the proposed methods are reliable for general reward hacking detection.

Action items.

- [science] The claim of ‘reproducible’ hacking relies on a single policy model (Qwen3-4B) and a single training seed per bias type. To support the generalizability of the onset times (Table 1) and the robustness of the detection agent (Table 3), the authors must report results across multiple random seeds ($n \geq 3$) or explicitly acknowledge the lack of variance analysis as a major limitation.
- [science] The definition of ‘canonical onset’ (Section 2.3) relies on a threshold sweep ($\Delta_{gap} \in \{0.08, 0.10, 0.12\}$) without reporting the sensitivity of the onset step to these specific hyperparameters. The authors should provide a sensitivity analysis or justify why the chosen thresholds are robust against small perturbations.
- [science] The detection agent evaluation (Table 3) compares RHDA against baselines but lacks statistical significance testing (e.g., confidence intervals or p-values) for the reported differences in onset localization error ($\sum d_p$). Given the small number of test cases (6 runs), the authors should clarify if the observed improvements are statistically significant or anecdotal.

Statistical Analysis

Scrutinizes the statistics — appropriateness of tests, multiple-comparison handling, confidence intervals, model assumptions, and the reproducibility of the analyses.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_statistical_analysis.md

The paper presents a rigorous framework for analyzing reward hacking, but the statistical reporting requires strengthening to fully support the quantitative claims.

First, uncertainty quantification is missing for key metrics. Table 1 reports Odds Ratios (OR) linking bias entanglement to onset time (e.g., OR=0.53 for self-praise on VerInstruct). Without confidence intervals or standard errors derived from the underlying contingency tables, it is unclear if the observed correlation between OR and onset delay is statistically robust or driven by noise. Similarly, Table 2 reports generation success ratios (e.g., 100.00% for Lexical bias). While the sample size (300 trials) is noted, the absence of confidence intervals (e.g., Wilson score intervals) makes it difficult to compare the precision of these estimates across bias types, particularly for the 66.00% Format bias.

Second, the definition of “canonical onset” lacks statistical formalism. The paper defines onset via a “modal canonical step” derived from a threshold sweep (Appendix A). However, it does not specify the statistical test or change-point detection algorithm used to identify the “rising edge” of the shortcut prevalence $M(t)$. The “threshold-induced interval” is described heuristically; a more rigorous approach would involve defining a null hypothesis (e.g., random fluctuation) and reporting the p-value or false discovery rate associated with the detected onset step.

Third, claims of statistical significance in capability degradation are unsupported by data. Section 3.1 states that models exhibiting hacking showed “significant in-domain capability drops” (Table 3). However, the table only provides point estimates (e.g., 31.7 vs 23.7 for IFB Strict). No standard deviations, standard errors, or results of statistical tests (e.g., paired t-tests or non-parametric equivalents) are provided to validate the term “significant.” Given the small number of experimental runs ($n=1$ per condition implied by the single values), the authors must clarify if these are averages over multiple seeds or single runs, and provide appropriate error bars or test statistics.

Finally, the detection performance metrics in Table 4 (RHDA vs. baselines) report aggregate distances ($\sum d_p, \sum d_l$) but lack variance measures. To properly compare RHDA-Plus against baselines like CC-Sonnet, the authors should report the standard deviation of the localization errors across the six runs or perform a statistical test to confirm that the observed improvements are not due to chance.

Action items.

- [science] Report confidence intervals or standard errors for the Odds Ratios (OR) in Table 1 and the success ratios in Table 2. The current point estimates (e.g., OR=0.53, 100.00%) lack measures of uncertainty, making it impossible to assess the statistical significance of the correlation between OR and onset time or the precision of the exploitability estimates.
- [science] Clarify the statistical methodology for determining the ‘canonical onset’ (modal step) and the associated ‘threshold-induced interval’ in Table 1. The current description implies a heuristic threshold sweep; specify the statistical criteria (e.g., change-point detection, hypothesis testing) used to define the onset and justify the interval width.
- [science] Provide p-values or effect sizes for the capability degradation claims in Section

3.1 (Table 3). The text states ‘significant in-domain capability drops’ for hacked models, but no statistical test (e.g., t-test, Mann-Whitney U) or variance metrics are reported to support this significance claim against the baseline.

Writing Quality

Reads the manuscript purely as prose — clarity, flow, sentence-level grammar, paragraph cohesion, and overall readability — setting the scientific content aside.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_writing_quality.md

The manuscript is generally well-written, with a clear logical flow from the problem definition to the proposed environment, analysis, and detection system. The technical prose is precise, and the mathematical formulations are clearly presented. However, there are a few areas where the writing quality and structural integrity need attention before final publication.

First, the most critical issue is the apparent duplication of entire sections in the appendices. The sections titled “Reproducibility: Models, Compute, and Infrastructure,” “Artifacts,” and “Training Dynamics of Non-Hacking Settings” appear verbatim in two separate locations within the provided source (specifically, they are repeated in the content labeled e001 and e002). This suggests a compilation error or a failure to merge source files correctly. This redundancy disrupts the reading experience and must be resolved by consolidating these sections into single, unique entries.

Second, while the definition of “Canonical onset” in Section 2.3 is conceptually clear, it lacks immediate operational detail. The text mentions “smoothed signals” and “thresholds” without specifying the smoothing window or the threshold values in the main body. While the appendix provides these details, the main text should include a brief parenthetical reference (e.g., “see Appendix A for smoothing parameters”) or a concise definition to ensure the metric is fully understandable without constant cross-referencing.

Finally, there is a potential nomenclature issue with the model identifier “Qwen3.5-397B-A17B.” The “397B” figure is highly unusual for a standard model release and may be a typo or a specific internal code that is not widely recognized. The authors should verify this identifier against the official model documentation to ensure accuracy and avoid confusing readers who may not be familiar with this specific naming convention.

Overall, the paper is strong, but these structural and clarity issues should be addressed to meet the high standards of publication.

Action items.

- [writing] The manuscript contains significant structural duplication in the appendices. Sections ‘Reproducibility’, ‘Artifacts’, and ‘Training Dynamics of Non-Hacking Settings’ appear twice (once in e001 and again in e002) with nearly identical text. This suggests a copy-paste error during compilation or merging of source files. The authors must consolidate these into single, unique sections to ensure professional presentation.

- [writing] In Section 2.3 (Quantifying the Onset of Reward Hacking), the definition of ‘Canonical onset (CO)’ states it is the ‘modal step where smoothed signals exceed thresholds,’ but the specific smoothing parameters or the exact thresholding logic are not defined in the main text. While details may be in the appendix, the main text should briefly specify the smoothing window size or refer explicitly to the appendix equation to ensure the definition is self-contained and reproducible.
- [writing] The phrase ‘Qwen3.5-397B-A17B’ appears in the text (e.g., Table 3 caption and Appendix). The ‘397B’ parameter count is likely a typo or a placeholder for a specific model version, as this number is non-standard and potentially confusing. The authors should verify the exact model identifier and ensure it is consistent with the official model card or repository to avoid reader confusion.
