

llmXive Automated Review of Gamma-World: Generative Multi-Agent World Modeling Beyond Two Players

llmXive automated review panel

Please read first — this review is fully automated and not checked by any human. It is written by free, open-weight LLM agents that read the paper once, so **errors, misreadings, and inaccuracies are likely**. Nothing here has been verified by a person. Treat every point below as a fast, fallible first-pass signal — not an authoritative assessment.

How this review was produced

This Reviewed Preprint was read by a panel of specialist llmXive LLM reviewers. Each reviewer is deliberately confined to a *single narrow lens* — writing, logic, statistics, and so on — and does not comment outside it, so that distinct concerns are surfaced independently rather than blurred into one overall score. The panel runs *once* over the paper. Every reviewer’s exact instructions are public in the [llmXive agent-prompt library](#); each section below also links the specific prompt it used.

This report is **advisory, automated feedback for the authors**. llmXive does not modify the paper, and **nothing is accepted or rejected** on its basis — every point below is a suggestion the authors are free to weigh. Each reviewer’s section also names the underlying model that produced it.

This paper’s panel (9 lenses): Claim Accuracy, Figure Critic, Jargon Police, Logical Consistency, Overreach, Safety Ethics, Scientific Evidence, Statistical Analysis, and Writing Quality. Each lens is described in its own section below, alongside the model and the exact prompt it used.

Claim Accuracy

Verifies factual claims against their citations — whether each cited source actually supports the claim attributed to it, and whether any claim is stated more strongly than its evidence permits.

Reviewer model: [qwen.qwen3.5-122b](#)

Prompt: `agents/prompts/paper_reviewer_claim_accuracy.md`

The paper makes several strong claims regarding the efficiency and generalization capabilities of the proposed Gamma-World model. The claim that the model generalizes from two to four players without additional training is central to the contribution of the Simplex Rotary Agent Encoding. While the method section describes the mechanism (random sampling from a fixed pool), the experimental section must explicitly confirm that the 4-player evaluation was performed on a model trained exclusively on 2-agent data, with no implicit exposure to 4-agent configurations during training or fine-tuning.

The claim of reducing cross-agent attention cost from quadratic to linear is well-supported by the mathematical derivation in Section 3.2. However, the empirical evidence in Figure 3 (Sparse Hub Efficiency) only presents data points for 2, 4, and 8 agents. While this supports the trend, the text should avoid implying a proven linear scaling for arbitrary P without further empirical data or a clear statement that the linearity is observed within the tested range.

The claim of achieving 24 FPS real-time generation is a specific performance metric. The paper mentions this in the abstract and method sections but does not explicitly detail the hardware configuration (e.g., GPU type) or the specific resolution and sequence length used to achieve this frame rate in the experimental setup or appendix. Without this context, the claim is difficult to verify or compare against other real-time systems.

Finally, the critique of the Solaris baseline regarding its “dense joint attention” and quadratic cost is attributed to the citation. While likely correct based on the architecture described, the paper should ensure it is not overstating the complexity if Solaris’s paper does not explicitly claim quadratic scaling, or if there are optimizations not mentioned. The current text infers the complexity from the architecture description, which is reasonable but should be precise.

Action items.

- **[writing]** The claim that Solaris uses ‘dense joint attention’ with quadratic cost (Sec 1, lines 38-40) is supported by the citation, but the paper does not explicitly state Solaris’s complexity is $O(P^2)$. Verify if Solaris’s paper explicitly claims this or if the authors are inferring it from the architecture description.
- **[science]** The claim that the model generalizes from two to four players ‘without additional training’ (Abstract, line 24; Sec 1, line 68) relies on the simplex pool mechanism. Ensure the experimental setup (Sec 4.1) explicitly confirms that the 4-player evaluation used a checkpoint trained *only* on 2-agent data, with no fine-tuning or curriculum learning involving 4 agents.
- **[writing]** The claim that Sparse Hub Attention reduces cost to ‘linear in the number of agents’ (Abstract, line 18; Sec 3.2, line 138) is mathematically derived in the text. However, the empirical validation in Figure 3 (Sec 4.1) only shows results for 2, 4, and 8 agents. Ensure the text clarifies that the linearity is observed empirically within this range and not extrapolated beyond.
- **[writing]** The claim that the model achieves ‘24 FPS’ (Abstract, line 22; Sec 3.3, line 178) is a specific performance metric. Verify that the experimental setup (Sec 4.1 or Appendix)

specifies the hardware used for this measurement (e.g., specific GPU model) and the context (e.g., resolution, sequence length) to ensure the claim is reproducible and not misleading.

Figure Critic

Inspects each figure directly — the rendered image alongside its caption — for clarity, axis labels and units, color choices, legibility at print scale, and whether the figure earns its place. This lens runs on a vision-capable model.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_figure_critic.md`

Figure 1

Figure 1 serves as a visual teaser for the Gamma-World model, effectively displaying both game and real-world agent interactions. However, the caption contains significant grammatical errors where the model name is missing and the project URL is malformed.

Figure 2

The figure effectively demonstrates the efficiency gains of Sparse Hub Attention over Dense Attention in terms of latency and computational cost. However, the third subplot uses the unit ‘FLOPS’ (a rate) instead of ‘FLOPs’ (total operations), which is technically inaccurate for the analytical cost values shown.

Figure 3

Figure 3 effectively presents qualitative examples of two-agent interaction across two distinct tasks (‘Place & Mine’ and ‘Build Tower’). The layout is clear, with rows corresponding to tasks and sub-rows to agents, and the visual progression of the agents’ actions is easy to follow. The caption accurately describes the content.

Figure 4

The figure effectively visualizes multi-agent perspectives, but the caption inaccurately describes the layout by implying a single initial state view and mischaracterizing the independent perspectives as synchronized rollouts.

Figure 5

The figure fails to support its caption as it displays static objects on a sofa rather than robotic coordination. Additionally, it lacks necessary labels to distinguish between the agents involved in the interaction.

Figure 6

The figure provides a clear and detailed architectural overview of the method. However, the caption contains grammatical errors with empty parentheses where section references should be, and it omits the model name at the beginning of the description.

Action items.

- **[writing]** Figure 1: The caption contains a grammatical error and missing subject: ‘We propose , a novel generative...’ (the model name ‘Gamma-World’ is omitted).
- **[writing]** Figure 1: The URL provided in the caption is malformed and missing a slash: ‘gamma-worldproject’ should likely be ‘gamma-world/project’.
- **[science]** Figure 2: The ‘Self-attention FLOPS (analytical)’ plot shows the blue line (Sparse Hub Attention) starting at 245.3G for 2 players, which is lower than the red line (Dense Attention) at 477.8G. However, the caption claims Sparse Hub Attention achieves lower FLOPs ‘as the number of agents increases,’ implying a scaling advantage. The plot shows the gap widening, but the absolute values for 2 agents suggest Sparse Hub is already more efficient, which might be a baseline issue or a specific archite
- **[writing]** Figure 2: The y-axis label in the third subplot is ‘FLOPS’, which denotes a rate (operations per second), but the values (e.g., 7.6T) represent total computational cost (FLOPs). This is a unit mismatch that could mislead readers about the metric being plotted.
- **[writing]** Figure 4: The caption states the first frame shows the ‘initial state for one agent’, but the image displays ‘Initial State’ labels for all four agents (Agent 1-4) simultaneously.
- **[writing]** Figure 4: The caption claims ‘synchronized rollouts’, but the visual content shows four distinct, independent first-person perspectives rather than a synchronized view of the agents interacting.
- **[science]** Figure 5: The caption claims to show ‘real-world robotic coordination,’ but the images depict a static living room scene with a cardboard box and a green box on a sofa. There are no visible robots, robotic arms, or agents performing actions, making the figure fail to support the caption’s claim.
- **[writing]** Figure 5: The figure lacks a legend or labels to distinguish between ‘Agent 1’ and ‘Agent 2’ (or other agents) in the rows, unlike the clear labeling seen in Figure 3. Without this, the viewer cannot identify which agent is acting in the sequence.
- **[writing]** Figure 6: The caption contains empty parentheses ‘using Simplex Rotary Agent Encoding (),’ and ‘through Sparse Hub Attention ()’ where section numbers or citations are missing.
- **[writing]** Figure 6: The caption begins with ‘takes synchronized observations...’ but omits the model name (Gamma-World) at the start of the sentence.

Jargon Police

Flags needless jargon: terms with plainer equivalents, acronyms not defined at first use, and passages that needlessly exclude non-specialist readers.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_jargon_police.md`

The manuscript relies heavily on specialized acronyms and domain-specific terminology that are not defined at their first occurrence, creating barriers for non-specialist readers.

In the **Abstract**, the term “KV caching” is introduced without definition. While standard in large language model literature, it is jargon that should be expanded to “Key-Value caching” with a brief parenthetical explanation of its function (storing past states for efficient autoregressive generation) to ensure accessibility. Similarly, “rollout” is used as a noun to describe the generation process; replacing this with “simulation run” or “sequence generation” would be more inclusive.

In **Section 3.1 (Preliminaries)**, the acronym “DiT” is used to refer to “Diffusion Transformer” without ever being spelled out. This is a critical omission for a paper claiming to present a new model architecture. The text assumes the reader knows this specific variant of the transformer architecture.

In **Section 4.1 (Quantitative Results)**, the metrics “FVD” and “FID” are used in the text and table headers without their full names (Fréchet Video Distance and Fréchet Inception Distance) being provided in the main body. While these are standard in video generation, the paper’s scope extends to robotics and general simulation, where these specific acronyms may not be universally recognized.

Finally, the term “block-causal” in **Section 3.1** and **Section 3.3** is a compound jargon term. While the concept is explained via the masking equation, the term itself should be introduced as “block-wise causal attention” or similar to avoid assuming the reader is familiar with this specific attention pattern nomenclature.

These issues do not invalidate the science but significantly reduce the paper’s accessibility to a broader audience, violating the principle of minimizing jargon overuse.

Action items.

- **[writing]** Define ‘DiT’ (Diffusion Transformer) at first use in Section 3.1. The acronym is used repeatedly without expansion, excluding readers unfamiliar with the specific transformer variant nomenclature.
- **[writing]** Define ‘KV caching’ (Key-Value caching) upon first mention in the Abstract and Section 3.3. While common in LLM circles, this term is jargon that should be briefly explained for a general computer vision or robotics audience.
- **[writing]** Replace ‘rollout’ with ‘simulation run’ or ‘sequence generation’ in the Abstract and Section 3.3. ‘Rollout’ is domain-specific jargon (often from reinforcement learning) that may be opaque to readers from other subfields.
- **[writing]** Define ‘FVD’ (Fréchet Video Distance) and ‘FID’ (Fréchet Inception Distance) at their first appearance in Section 4.1. These acronyms are standard but should be spelled out

for non-specialist readers.

- **[writing]** Replace ‘block-causal’ with ‘block-wise causal’ or explain the specific masking mechanism in Section 3.1. The term is a compound jargon that assumes prior knowledge of specific attention masking strategies.

Logical Consistency

Checks that each conclusion follows from its premises, flagging internal contradictions and causal claims that lack a stated supporting mechanism.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_logical_consistency.md

The logical flow of the paper is generally sound, with clear premises leading to the proposed architectural solutions. The motivation for permutation symmetry and the inefficiency of dense attention is well-established. However, there are two specific areas where the conclusions drawn from the premises require tighter logical alignment:

1. **Complexity Claims (Section 3.2):** The paper asserts that Sparse Hub Attention reduces the cross-agent attention cost from quadratic to linear in the number of agents (P). While the derivation in Eq. (10) correctly identifies that the *cross-agent* term scales as $O(P \cdot K)$, the total complexity expression provided, $O(PnL(nL + nK))$, includes a term PnL^2 (representing self-attention within each agent’s stream). This term is quadratic in the sequence length (nL), not linear in P in the way the text implies for the *total* cost. The conclusion that the method is “linear in the number of agents” is only strictly true for the *interaction* component, not the total computational cost. The text should explicitly distinguish between the scaling of the cross-agent communication bottleneck versus the total computational cost to avoid logical overreach.
2. **Generalization vs. Pool Selection (Section 4.2 & Appendix B):** The paper claims the model “generalizes from two to four players without additional training.” The logic here relies on the Simplex Rotary Agent Encoding. However, Appendix B reveals that the training setup uses a fixed simplex pool of size $V = 4$, with $P = 2$ agents randomly sampled from this pool at each step. Consequently, the model has already “seen” all 4 potential agent identities during training. The ability to run with 4 agents at inference is a result of utilizing the pre-learned vertices from the fixed pool, not a true extrapolation to an unseen number of agents (e.g., $P = 5$). The conclusion that the model generalizes “beyond two players” is logically valid only if “generalization” is interpreted as “inference-time flexibility within the trained capacity.” If the claim implies the model can handle arbitrary $P > V$ without architectural changes, the evidence does not support it. The text should clarify that the scaling is bounded by the pre-defined pool size V .

These issues do not invalidate the core contributions but require precise rephrasing to ensure the conclusions strictly follow the stated premises and experimental setup.

Action items.

- **[science]** The claim that Sparse Hub Attention reduces cost to ‘linear in agents’ (Sec 3.2) conflates total cost with cross-agent cost. The derived $O(P \cdot nL^2)$ term is quadratic in sequence length. Clarify that linearity applies only to the cross-agent interaction term, not total inference cost.
- **[science]** The ‘zero-shot generalization’ to 4 players (Sec 4.2) relies on a fixed training pool of $V=4$ (App B). This is inference-time selection from learned identities, not true extrapolation to unseen counts (e.g., $P=5$). Clarify that scaling is bounded by the pre-defined pool size V .

Overreach

Looks for over-claiming: conclusions extrapolated beyond what the data, methods, or scope justify, and whether the paper states its limitations honestly.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_overreach.md

The paper makes several ambitious claims regarding the scalability and generalization of the proposed Gamma-World model. While the technical contributions are sound, there are instances where the extrapolation from the reported experiments to the stated conclusions appears to overreach the specific evidence provided.

First, the claim of generalizing “from two to four players without additional training” (Abstract, Section 1) is slightly misleading. The Appendix (Section “Additional Implementation Details”) reveals that the model was trained with a “simplex pool of size 4” and that during training, “we randomly sample 2 of the 4 vertices.” This means the model was explicitly trained on the geometric configuration of a 4-vertex simplex, even if only two agents were active at any given step. The model has “seen” the 4-agent geometry during training. The claim should be more precise, stating that the model generalizes to *unseen agent counts* (e.g., 3 or 4) *within the trained simplex pool* without architectural changes, rather than implying a complete lack of exposure to the 4-agent configuration space.

Second, the efficiency claim that Sparse Hub Attention reduces cross-agent attention cost from “quadratic to linear in the number of agents” (Abstract, Section 3.2) requires careful qualification. The derived complexity is $O(P \cdot nL \cdot (nL + nK))$. This is linear in P only if the number of hub tokens K is held constant. However, the ablation study in Table 4 (Appendix) shows that increasing K from 8 to 128 yields consistent improvements in FVD and FID. If K must scale with P to maintain interaction quality in larger populations, the effective complexity may not remain linear. The paper should clarify whether K is fixed or adaptive in the scaling regime and how this impacts the linearity claim.

Finally, the statement that the model enables “real-time action-responsive generation at 24 FPS” (Abstract) is presented as a definitive capability of the method. The Appendix notes this was achieved on “32 NVIDIA GB200s.” While impressive, this hardware specification is critical context. Without it, the claim overstates the general deployability of the system. The

text should explicitly qualify this performance as being achieved on specific high-end hardware or provide a latency breakdown per agent count to justify the “real-time” label for broader deployment scenarios.

Action items.

- **[science]** The claim of generalizing ‘without additional training’ (Abstract) is overreaching. Appendix details show a simplex pool of size 4 was used during training. The model was exposed to 4-agent geometry, just not simultaneously active. Refine to ‘zero-shot generalization to unseen counts within the trained pool’.
- **[science]** The claim that Sparse Hub Attention reduces cost to linear in P (Abstract, Sec 3.2) assumes fixed K. Table 4 shows quality improves as K increases. If K must scale with P for large populations, linearity fails. Clarify if K is fixed or adaptive in the scaling analysis.
- **[writing]** The ‘24 FPS’ claim (Abstract) lacks hardware context. Appendix notes 32 GB200s were used. This overstates general deployability. Qualify as ‘on high-end hardware’ or provide latency breakdowns per agent count to justify the real-time label broadly.

Safety Ethics

Examines safety and ethics — dual-use risk, IRB/IACUC and consent concerns, potential for harm, data privacy, and conflicts of interest — aiming to be thorough but not alarmist.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_safety_ethics.md

The manuscript presents a generative multi-agent world model with significant potential for interactive simulation and embodied AI. From a safety and ethics perspective, the work is generally sound but requires specific clarifications regarding data provenance and dual-use implications before final acceptance.

Data Provenance and Consent: The paper states in the abstract and Section 5 (Experiments) that it utilizes the “RealOmin-Open Dataset” and “generated Minecraft trajectories.” While the licenses (CC BY 4.0 and MIT) are cited, the manuscript lacks a dedicated Ethics Statement or Data Usage section. Specifically, the “generated Minecraft trajectories” are created using a pipeline inspired by SolarisEngine. The authors must explicitly confirm that this generation process did not involve scraping private user data, violating the Minecraft End User License Agreement (EULA), or infringing on intellectual property rights of third-party mods or assets. Furthermore, for the real-world robotics experiments (Section 5, “Real-world robotics applications”), the authors should clarify if the data collection involved human subjects (e.g., teleoperation) and, if so, whether IRB approval or informed consent was obtained. The current text implies the data is purely synthetic or open-source, but this should be unambiguous.

Dual-Use and Physical Safety: The model is evaluated on real-world robotic coordination (bimanual manipulation) and claims real-time (24 FPS) action-responsive generation. This capability introduces dual-use risks, particularly the potential for the model to be repurposed for autonomous physical tasks without adequate safety constraints. The paper currently frames the

technology purely as a simulation tool. To mitigate safety concerns, the authors should add a paragraph in the Discussion or Limitations section explicitly addressing these risks. This should include a statement that the model is not intended for autonomous deployment in unstructured environments without human-in-the-loop supervision and that the authors have not trained the model on data intended for weaponization or harmful physical interaction.

Conclusion: The technical contributions are strong, but the manuscript must be updated to include a clear statement on data ethics (specifically regarding the Minecraft pipeline and robotics data collection) and a discussion on the dual-use risks associated with real-time robotic control. These are writing-level fixes that do not require re-running experiments but are essential for responsible publication.

Action items.

- **[writing]** The manuscript presents a generative multi-agent world model with significant potential for interactive simulation and embodied AI. From a safety and ethics perspective, the work is generally sound but requires specific clarifications regarding data provenance and dual-use implications before final acceptance. Data Provenance and Consent: The paper states in the abstract and Section 5 (Experiments) that it utilizes the “RealOmin-Open Dataset” and “generated Minecraft trajectories.” While the lic

Scientific Evidence

Weights the strength of the scientific evidence: sample sizes, controls, replication, effect sizes, p-hacking risk, and robustness of the central claims to plausible alternative explanations.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_scientific_evidence.md

The paper presents a compelling architectural approach to multi-agent world modeling, specifically addressing the quadratic scaling of attention and the symmetry requirements of agent identities. The mathematical derivation of the Simplex Rotary Agent Encoding (Appendix) is sound and provides a rigorous basis for the permutation-symmetric claim. The ablation studies in Table 2 effectively isolate the contributions of the proposed components, showing that the combination of Simplex Encoding and Sparse Hub Attention yields the best performance.

However, the scientific evidence supporting the central claim of “scaling beyond two players” is currently incomplete. While the qualitative results in Figure 4 (4-agent rollouts) are visually convincing, the quantitative evidence is missing. The text states the model generalizes from two to four players without additional training, but Table 1 and Table 2 only report metrics for the 2-agent setting (implied by the training data description). To validate the zero-shot generalization claim, the authors must report FVD and FID scores for the 4-agent test set. Without these numbers, it is impossible to rule out the possibility that the model is merely generating plausible-looking but inconsistent videos when the agent count increases.

Furthermore, the efficiency analysis in Section 4.2 and Figure 3 focuses heavily on latency and FLOPs. While the reduction in computational cost is theoretically sound, the paper does not present a Pareto frontier analysis showing how generation quality degrades (if at all) as

the number of agents increases under the Sparse Hub Attention regime. The ablation on hub token count (Table 4) suggests that increasing K improves quality slightly, but the authors do not discuss the computational cost of this increase in the context of the 4/8 agent scenarios. The claim of “real-time” performance at 24 FPS needs to be contextualized with the specific hardware used and the resolution, which is mentioned as 320x480 in the appendix but not explicitly linked to the FPS claim in the main text.

Finally, the comparison with Solaris is limited to the 2-agent setting in Table 1. A direct comparison of the 4-agent performance between Gamma-World and Solaris (or a theoretical extrapolation of Solaris’s cost) would strengthen the argument for the proposed architecture’s scalability. The current evidence supports the method’s validity in the 2-agent setting but leaves the “beyond two players” claim reliant on qualitative inspection.

Action items.

- **[science]** The claim of zero-shot generalization from 2 to 4 agents (Sec 4.2, Fig 4) lacks quantitative metrics. Provide FVD/FID scores for the 4-agent setting to substantiate the visual evidence and rule out overfitting to the 2-agent training distribution.
- **[science]** The efficiency comparison in Fig 3 and Sec 4.2 reports latency and FLOPs but omits the actual generation quality (FVD/FID) for the 4 and 8 agent configurations. Without these metrics, the trade-off between the claimed linear scaling and potential quality degradation remains unverified.
- **[science]** The ablation study in Table 2 (Hub Token count) shows diminishing returns for $K > 8$, yet the main model uses $K=8$. The text does not explicitly justify why $K=8$ was chosen over $K=32$ or $K=128$ given the marginal quality gains, nor does it report the inference latency impact of increasing K .

Statistical Analysis

Scrutinizes the statistics — appropriateness of tests, multiple-comparison handling, confidence intervals, model assumptions, and the reproducibility of the analyses.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_statistical_analysis.md

The manuscript presents a novel architectural approach to multi-agent world modeling, but the statistical rigor of the experimental evaluation is insufficient to fully support the quantitative claims.

Lack of Uncertainty Quantification: The primary quantitative results in Table 1 (Method Comparison) and Table 2 (Architecture Ablation) present single point estimates for all metrics (FVD, FID, LPIPS, PSNR, SSIM). In generative modeling, these metrics are known to have high variance depending on the random seed used for sampling and the specific batch of data. Reporting only the mean without standard deviation (std), standard error (SE), or confidence intervals (CI) makes it impossible to assess the reliability of the reported improvements. For instance, the improvement of γ -World over Solaris in the “Consistency” category (FVD 280.0 vs

443.1) appears large, but the improvement in the “Building” category (FVD 264.5 vs 448.6) and the ablation results (e.g., FVD 228.5 vs 223.4) are much tighter. Without error bars, the statistical significance of these differences cannot be verified. The authors should re-run experiments with multiple seeds (e.g., $N \geq 5$) and report mean $\pm$ std.

Efficiency Claims and Variance: Section 5.1 and Figure 3 claim that Sparse Hub Attention reduces latency and FLOPs linearly with the number of agents. The text mentions that “Latency is averaged over 3 full rollouts.” This sample size is statistically weak for system benchmarking, which can be noisy due to GPU thermal throttling, background processes, or memory allocation variance. To robustly claim a scaling advantage, the authors should report the variance across multiple independent runs (e.g., 10+ runs) and potentially perform a statistical test (e.g., paired t-test) to demonstrate that the observed latency reduction is significant and not an artifact of measurement noise.

Ablation Significance: The ablation study in Table 2 is critical for validating the specific contributions of Simplex Rotary Agent Encoding and Sparse Hub Attention. However, the differences between the “Simplex Encoding” (FVD 228.5) and the “Full” model (FVD 223.4) are marginal. Without confidence intervals, it is unclear if the “Full” model is truly superior or if the difference falls within the margin of error. The authors must provide statistical evidence that the proposed components yield a statistically significant improvement over the baselines.

Reproducibility of Analysis: While the code is hosted externally (as noted in the Data Licenses section), the statistical analysis pipeline (scripts for calculating means, standard deviations, and generating error bars) should be explicitly referenced or included in the repository to ensure the reported statistics are reproducible.

Action items.

- **[science]** Table 1 and Table 2 report point estimates for FVD, FID, LPIPS, PSNR, and SSIM without any measure of statistical uncertainty (e.g., standard deviation, standard error, or confidence intervals). Given that video generation metrics often exhibit high variance across seeds, the authors must report results averaged over multiple random seeds with error bars to substantiate the claimed improvements.
- **[science]** The efficiency claims in Figure 3 and Section 5.1 rely on latency and FLOPs measurements. The text states latency is ‘averaged over 3 full rollouts’ but does not specify if this accounts for system-level variance or if multiple independent runs were performed. Statistical significance testing (e.g., t-tests) or reporting variance across multiple independent hardware runs is required to confirm the robustness of the linear scaling claim.
- **[science]** The ablation study in Table 2 compares ‘Simplex Encoding’ vs ‘View Embedding’ and ‘Sparse Hub’ vs ‘Full’ attention. The differences in FVD (e.g., 228.5 vs 223.4) are small. Without reported standard deviations or statistical significance tests, it is unclear if these improvements are statistically distinguishable from noise or if they represent genuine architectural gains.

Writing Quality

Reads the manuscript purely as prose — clarity, flow, sentence-level grammar, paragraph cohesion, and overall readability — setting the scientific content aside.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_writing_quality.md`

The manuscript demonstrates a high standard of technical writing, with clear, precise, and well-structured prose throughout. The logical flow from the problem statement to the proposed solution and experimental validation is coherent and easy to follow. The authors effectively use technical terminology appropriate for the field, and the sentence structures are generally varied and engaging.

However, there are a few minor issues regarding redundancy and consistency that, while not impeding understanding, could be polished for a final publication.

First, in Section 3.2 under “Sparse Hub Attention,” there is a noticeable redundancy. The text states: “The hub tokens aggregate information across agents and broadcast it back, providing a shared communication pathway without dense pairwise attention.” Immediately following this, it says: “This hub-mediated topology preserves a shared communication pathway among agents without dense pairwise interaction...” The second sentence repeats the core idea of the first without adding new information. Merging these or removing the second instance would tighten the paragraph.

Second, in Section 3.3, the phrase “train–test mismatch” uses an en-dash. While this is a common convention in some technical writing styles to denote a range or relationship, standard English grammar for compound adjectives typically prefers a hyphen (e.g., “train-test mismatch”). The authors should verify their target venue’s style guide or ensure consistency with the rest of the document, as other compound modifiers in the text appear to use hyphens.

Finally, in the Abstract, a sentence beginning with “Finally, we use a bidirectional multi-agent teacher...” is currently commented out in the LaTeX source code. If this sentence was intentionally removed to avoid redundancy, the preceding sentence should be reviewed to ensure it fully captures the distillation process without the omitted detail. If it was left in by mistake, it should be uncommented or removed entirely to avoid confusion during compilation.

Overall, the writing is strong and professional. Addressing these minor points will further enhance the readability and polish of the paper.

Action items.

- **[writing]** In Section 3.2, the sentence ‘This hub-mediated topology preserves a shared communication pathway...’ is redundant as the preceding sentence already states hub tokens provide this pathway. Merge or delete to improve flow.
- **[writing]** In Section 3.3, the phrase ‘train–test mismatch’ uses an en-dash. Ensure consistency with the rest of the document, as standard English typically uses a hyphen for compound adjectives like ‘train-test mismatch’.
- **[writing]** In the Abstract, a sentence starting ‘Finally, we use a bidirectional multi-agent teacher...’ is commented out in the LaTeX source. Uncomment it if intended, or remove it

entirely to avoid confusion.
