

llmXive Automated Review of From Activation to Causality: Discovery of Causal Visual Representations in the Human Brain

llmXive automated review panel

Please read first — this review is fully automated and not checked by any human. It is written by free, open-weight LLM agents that read the paper once, so **errors, misreadings, and inaccuracies are likely**. Nothing here has been verified by a person. Treat every point below as a fast, fallible first-pass signal — not an authoritative assessment.

How this review was produced

This Reviewed Preprint was read by a panel of specialist llmXive LLM reviewers. Each reviewer is deliberately confined to a *single narrow lens* — writing, logic, statistics, and so on — and does not comment outside it, so that distinct concerns are surfaced independently rather than blurred into one overall score. The panel runs *once* over the paper. Every reviewer's exact instructions are public in the [llmXive agent-prompt library](#); each section below also links the specific prompt it used.

This report is **advisory, automated feedback for the authors**. llmXive does not modify the paper, and **nothing is accepted or rejected** on its basis — every point below is a suggestion the authors are free to weigh. Each reviewer's section also names the underlying model that produced it.

This paper's panel (9 lenses): Claim Accuracy, Figure Critic, Jargon Police, Logical Consistency, Overreach, Safety Ethics, Scientific Evidence, Statistical Analysis, and Writing Quality. Each lens is described in its own section below, alongside the model and the exact prompt it used.

Claim Accuracy

Verifies factual claims against their citations — whether each cited source actually supports the claim attributed to it, and whether any claim is stated more strongly than its evidence permits.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_claim_accuracy.md`

The review focuses on the accuracy of factual claims and the support provided by citations within the manuscript.

Factual Accuracy of Model Claims A significant factual discrepancy exists in Section 3 (“The BrainCause Framework”), where the authors state: “We automatically constructed a list of 260 concepts using ChatGPT (GPT-5)~\cite{openai2025gpt5systemcard}.” As of the current scientific timeline (2025/2026), GPT-5 is not a publicly available or standard model for such tasks, and the citation points to a “System Card” which may be speculative or non-existent in the public domain. If the authors used GPT-4o or another available model, this claim is factually incorrect and misrepresents the experimental reproducibility. If GPT-5 was indeed used in a private beta, the citation must be valid and the claim qualified. This requires immediate correction to ensure the methodology is accurately described.

Precision of Statistical Claims The Abstract and Introduction claim that “over 70%” of activation-based localizations are false positives. The Results section (Section 4.1, paragraph “Activation-Based Regions Have High False Positive Rate”) provides a more precise figure: “nearly 70%” and later “73.4%”. While the difference is minor, the phrase “over 70%” in the abstract is technically accurate ($73.4 > 70$), but the phrasing “nearly 70%” in the body creates a slight inconsistency in tone. More importantly, the claim that “over 70% failing... despite achieving high activation scores” is supported by the data, but the authors should ensure the abstract’s “over 70%” aligns with the specific “73.4%” figure to avoid any ambiguity about the magnitude of the effect.

Citation Support for Methodological Details The paper cites `Bao2025MindSimulator` to support the description of the MindSimulator baseline method, specifically that it “retrieves images from COCO using CLIP scores” (Section 4.1). While the citation is appropriate for the method’s name, the specific claim about the dataset (COCO) and the retrieval mechanism (CLIP) must be explicitly verifiable in the cited preprint. If the preprint describes a different dataset or retrieval method, this attribution is inaccurate. Given that the authors also mention using a “120K unlabeled images from COCO” pool in their own setup (Appendix), there is a risk of conflating the baseline’s original setup with the authors’ modified setup. The text should clarify if the MindSimulator baseline was re-implemented exactly as described in the paper or if the authors adapted it, ensuring the citation accurately reflects the source of the specific implementation details.

Conclusion The core scientific claims regarding the superiority of causal discovery over activation-based methods are supported by the presented data (Tables 1, 2, 3). However, the specific claim regarding the use of “GPT-5” is a factual error that must be corrected. Additionally, minor clarifications on the precision of the false positive rate and the exact implementation

details of the baseline method are recommended to ensure strict adherence to factual accuracy.

Action items.

- **[writing]** The claim that 260 concepts were constructed using ‘ChatGPT (GPT-5)’ (Sec 3, line 1) is factually unsupported. GPT-5 is not a publicly released model as of the paper’s context (2025/2026), and the citation ‘openai2025gpt5systemcard’ refers to a system card that likely does not exist or is speculative. Authors must clarify the actual model used (e.g., GPT-4o) or remove the specific version claim to avoid misrepresentation of the experimental setup.
- **[writing]** The claim that ‘over 70% [of activation-based localizations] failing to exhibit concept-specific responses’ (Abstract, line 12; Intro, line 24) is slightly overstated based on the provided text. The Results section (Sec 4.1, ‘Activation-Based Regions Have High False Positive Rate’) explicitly states the rate is ‘nearly 70%’ and later specifies ‘73.4%’. While close, the abstract should align precisely with the specific statistic reported in the results to maintain strict factual accuracy.
- **[writing]** The citation ‘Bao2025MindSimulator’ is used to support the claim that MindSimulator ‘retrieves images from COCO using CLIP scores’ (Sec 4.1, line 3). However, the bibliography entry for Bao2025MindSimulator is an arXiv preprint. Authors should verify that the specific implementation details (COCO retrieval, CLIP usage) are explicitly described in that preprint and not conflated with other works, as the citation does not inherently prove the specific dataset source without the text of the paper.

Figure Critic

Inspects each figure directly — the rendered image alongside its caption — for clarity, axis labels and units, color choices, legibility at print scale, and whether the figure earns its place. This lens runs on a vision-capable model.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_figure_critic.md

Figure 1

Figure 1 effectively communicates the conceptual difference between prior activation-based methods and the proposed BrainCause approach. The visual flow from counterfactual generation to causal evaluation is clear, and the caption accurately describes the logic of distinguishing false positives from true causal regions.

Figure 2

Figure 2 is a clear and well-structured pipeline diagram that effectively visualizes the data generation process described in the caption. All components, including the specific models used

(Gemma, Flux, Qwen) and the three stimulus categories, are explicitly labeled and easy to follow.

Figure 3

The figure content (generated images with scores) fundamentally contradicts the caption’s description (brain regions/activation maps). Additionally, the specific metric for the displayed numerical scores is undefined, and the semantic negative examples lack clear visual correspondence to their paired positive stimuli.

Figure 4

The figure displays scatter plots of training scores versus evaluation scores but fails to visually demonstrate the ‘ranking’ or ‘reduction of false discoveries’ claimed in the caption. Additionally, the axis labels are inconsistent between panels and do not clearly support the evaluation-focused claim.

Figure 5

The figure effectively visualizes concept-specific causal scores on brain flatmaps with clear ROI outlines, but it lacks a colorbar to quantify the score values and the specific concept names are only implied by column headers rather than explicitly defined in the caption.

Figure 6

The figure effectively visualizes distinct voxel patterns for body and text concepts, but it lacks a colorbar to quantify the displayed scores and the caption does not explicitly link the specific concept images to their corresponding brain map panels.

Figure 7

The figure effectively demonstrates cross-subject consistency with clear layout and representative images, but the internal anatomical labels are illegible and the absence of a color scale prevents quantitative interpretation of the causal scores.

Figure 8

The figure effectively illustrates the contrast between broad activation patterns and selective causal maps, but the rotated row labels and illegible ROI text annotations significantly reduce readability and interpretability.

Figure 9

Figure 9 effectively visualizes the dataset coverage with clear histograms, but the x-axis labels on the top and bottom-left plots are slightly ambiguous regarding whether they represent the count value or the concept identifier, and the bottom-right x-axis label could be more precise

about the ‘pair’ unit.

Figure 10

The figure attempts to show failure cases in semantic-negative generation but lacks visual evidence of generation artifacts, presenting what appear to be standard photographs instead. Additionally, the rotated row labels on the left margin are difficult to read and poorly integrated with the image grid.

Figure 11

Figure 11 presents five p-value histograms as described, but fails to label which of the five ‘validation criteria’ each subplot represents, undermining interpretability. Additionally, the y-axis label is inconsistently applied across subplots.

Figure 12

The figure illustrates distinct spatial patterns for action concepts but lacks essential annotation, including a legend for the binary maps and anatomical labels for the brain regions.

Action items.

- **[science]** Figure 3: The caption describes the figure as showing ‘regions discovered by BrainCause’ and ‘regions discovered by an activation-based method’ (implying brain maps), but the rendered image displays generated images (e.g., ‘Market to mountains’, ‘Pizza’) with numerical scores. The visual content does not match the caption’s description of the data type.
- **[science]** Figure 3: The caption states the figure shows ‘high activation’ and ‘lower activation’, but the image displays numerical values (e.g., +1.72, -0.26) without specifying the metric (e.g., correlation, z-score, log-odds) or units, making the magnitude of ‘activation’ uninterpretable.
- **[writing]** Figure 3: The ‘Semantic negatives’ row in the top section contains images (e.g., sleeping person, office desk) that do not visually correspond to the ‘Market to mountains’ or ‘Party to empty room’ causal edit pairs above them, making the relationship between the positive and negative examples unclear.
- **[science]** Figure 4: The caption claims the figure shows ‘Causal ranking reduces false discoveries’ and compares BrainCause to activation-based methods, but the plot axes are labeled ‘Activation Train Score’ and ‘Causality Train Score’ (training metrics) rather than evaluation metrics. Furthermore, the plot displays raw scatter points without any ‘ranking’ visualization (e.g., a curve or threshold line) to demonstrate the reduction of false positives.
- **[writing]** Figure 4: The x-axis label in panel (a) is ‘Activation Train Score’ while panel (b) is ‘Causality Train Score’, yet the y-axis is ‘Causality Eval Score’ for both. This inconsistency in axis labeling (Train vs Eval) makes it unclear if the comparison is between training performance or evaluation performance.

- **[writing]** Figure 5: The caption states ‘three example concepts’ are shown, but the image displays three columns labeled ‘Animal Face’, ‘Food’, and ‘Tool’ without explicitly defining these as the specific concepts in the text.
- **[writing]** Figure 5: The caption mentions ‘warmer colors indicate higher concept-specific causal evidence’, but no colorbar or scale is provided to quantify the causal score values.
- **[writing]** Figure 6: The figure displays six brain maps corresponding to six concepts (Human Leg, Human Hand, Human Face, Symbolic Signs, Logo, Handwritten Text), but the caption only lists the concepts in text without explicitly mapping them to the specific panels (Left vs. Right) or providing a clear legend linking the top images to the bottom maps.
- **[writing]** Figure 6: The brain maps lack a colorbar or legend indicating the scale of the ‘causal scores’ or activation levels, making it impossible to determine the magnitude of the colored regions relative to the background.
- **[writing]** Figure 7: The text labels for the visual regions (e.g., ‘OPA’, ‘EBA’, ‘VWFA-1’) are extremely small and low-contrast against the background, making them illegible in the rendered image.
- **[writing]** Figure 7: The colorbar or scale indicating the specific range of ‘causal scores’ is missing; the caption describes warmer colors as higher evidence but provides no quantitative reference.
- **[writing]** Figure 8: The row labels ‘Activation Score’ and ‘Causal Score’ are rotated 90 degrees and placed outside the plot area, making them difficult to read and visually disconnected from the data rows.
- **[writing]** Figure 8: The brain flatmaps contain numerous small text labels (e.g., ‘OPA’, ‘EBA’, ‘VWFA-1’) that are illegible at the current resolution, hindering the ability to verify the caption’s claim about specific region suppression.
- **[writing]** Figure 9: The top histogram’s x-axis label (‘# Positive Examples per Target Concept’) and the bottom-left’s (‘# Negative Examples per Target Concept’) are ambiguous; the caption states these counts are ‘For each target concept,’ implying the x-axis should represent the count value (bin) and the y-axis the number of concepts, but the labels could be misread as the x-axis being the concepts themselves. Clarify axis labels to ‘Count of Examples’ (x) and ‘# of Target Concepts’ (y) for precision.
- **[writing]** Figure 9: The bottom-right plot’s x-axis label (‘# Successfully Retrieved Images per Semantic-Negative’) is slightly confusing given the y-axis is ‘# Semantic Negatives’; it implies the x-axis is the number of images retrieved for a single negative, but the caption says ‘for each target–negative pair’. While likely correct, the label could be clearer, e.g., ‘# Retrieved Images per Pair’.
- **[science]** Figure 10: The caption claims these are ‘semantic negatives’ that failed to exclude the target concept, but the images shown (e.g., ‘Sky’, ‘Reflection’) appear to be standard, high-quality photographs of the target concepts themselves rather than generated images

containing artifacts or failures. It is unclear if these are the ‘generated’ images or the ‘positive’ ground truth used for comparison, making the ‘failure’ claim visually unsubstantiated.

- **[writing]** Figure 10: The row labels (‘Image with lighting contrast’, ‘Sky’, ‘Image with reflection’) are rotated 90 degrees and placed on the far left, which is a poor layout choice that makes them difficult to read and visually disconnected from the specific images they describe.
- **[science]** Figure 11: The caption claims histograms show p-values for ‘five validation criteria,’ but only five subplots are shown without labels identifying which criterion corresponds to which plot, making it impossible to verify the claim or interpret the results.
- **[writing]** Figure 11: The y-axis label ‘# Concepts’ is present on the first subplot but missing from the other four, creating visual inconsistency and potential confusion about whether all plots share the same metric.
- **[science]** Figure 12: The maps lack a colorbar or legend defining the binary scale (e.g., 0 vs 1 or ‘negative’ vs ‘positive’), making it impossible to distinguish the background from the active voxels without relying on the caption.
- **[science]** Figure 12: The brain maps are unlabeled; there are no axis ticks, anatomical landmarks, or ROI outlines (unlike Figure 5) to identify the specific cortical regions shown.

Jargon Police

Flags needless jargon: terms with plainer equivalents, acronyms not defined at first use, and passages that needlessly exclude non-specialist readers.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_jargon_police.md

The manuscript makes a strong case for causal validation in visual neuroscience but relies heavily on specialized jargon and unexplained acronyms that may exclude non-specialist readers.

In the Abstract and Introduction, the term “fMRI” is used without definition. While common in the field, a broader audience requires the full term “functional magnetic resonance imaging” at first use. Similarly, in Section 4 (Results), the acronym “NSD” is introduced without spelling out “Natural Scenes Dataset,” which is a barrier to entry for readers unfamiliar with this specific dataset.

In Section 3.1 and Section 4.1, the acronym “VLM” is used to refer to “vision-language model.” This should be written out fully at the first instance. The same applies to “ROI” (Region of Interest) in Table 1 and Section 4.2, and statistical acronyms “TPR” and “FPR” in Section 4.1, which should be expanded to “true positive rate” and “false positive rate” respectively.

Finally, the phrase “causally validated” is used repeatedly. While precise, it borders on jargon-heavy phrasing. Alternatives like “causally confirmed” or “causally supported” might be slightly more accessible, though the primary issue remains the unexplained acronyms. Addressing these definitions will significantly improve the paper’s accessibility without sacrificing scientific

rigor.

Action items.

- **[writing]** Define ‘fMRI’ at first use in the Abstract and Introduction. While standard in neuroscience, it is jargon to general readers.
- **[writing]** Replace the acronym ‘NSD’ with ‘Natural Scenes Dataset’ at first mention in Section 4 (Results) and define it clearly.
- **[writing]** Replace the acronym ‘VLM’ with ‘vision-language model’ at first use in Section 3.1 and Section 4.1 to aid non-specialist readers.
- **[writing]** Replace the acronym ‘ROI’ with ‘region of interest’ in Table 1 and Section 4.2, or ensure it is defined earlier in the text.
- **[writing]** Replace the acronym ‘TPR’ and ‘FPR’ with ‘true positive rate’ and ‘false positive rate’ in Section 4.1, or define them immediately upon use.

Logical Consistency

Checks that each conclusion follows from its premises, flagging internal contradictions and causal claims that lack a stated supporting mechanism.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_logical_consistency.md

The paper presents a compelling argument for moving from activation-based to causal-based discovery of visual representations. However, there are logical gaps in the derivation of the selection criteria and the interpretation of the validation results.

First, the definition of the “causal score” in Section 3.2 (lines 235-238) creates a logical vulnerability. The authors define the causal score as the average of the semantic-negative and counterfactual scores and select voxels where this score is positive. Logically, a voxel that is unresponsive to *all* stimuli (low activation to positives and low activation to negatives) would yield a causal score near zero or positive (if noise favors negatives slightly less), yet it would not represent the concept. The text implies that high activation is a prerequisite, but the mathematical selection rule ($S_{causal} > 0$) does not strictly enforce a minimum activation threshold. Therefore, the conclusion that the selected voxels are “representations” does not necessarily follow from the stated selection mechanism.

Second, the claim in Section 4.1 that activation-based methods yield a ~70% false positive rate relies on the assumption that a negative causality score definitively proves a region is not a true representation. This logic holds only if the “semantic negatives” and “counterfactuals” are perfect controls. The paper admits in Appendix A.6 that semantic-negative generation fails for broad concepts (e.g., “sky” or “reflection”). If the negative generation fails (e.g., the “negative” image still contains the target concept), the causal score will be low, leading the method to classify a true positive as a false positive. The conclusion that these are “false positives” rather than “false negatives of the validation test” is not fully supported without a rigorous analysis of

the failure modes of the negative generation pipeline.

Finally, the statistical testing in Appendix A.7 (lines 630-640) compares the target concept score against a baseline of other concepts on the *same* region. Since the region was selected specifically to maximize the target score, this comparison is logically circular. The p-value tests whether the target is the *most* activating concept for that specific region, which is a tautology of the selection process. It does not logically prove that the region is causally specific to the target in a general sense, only that it is the best match among the tested concepts for that specific voxel set. The claim of “significance” requires a correction for the selection bias or a hold-out set that was not used in the region definition.

Action items.

- **[science]** The voxel selection rule ($S_{\text{causal}} > 0$) in Sec 3.2 does not logically enforce high activation. A silent voxel with low response to both positives and negatives yields a positive causal score but is not a representation. The conclusion that selected voxels represent the concept is unsupported without an explicit activation threshold.
- **[science]** The claim that 70% of activation-based findings are false positives (Sec 4.1) assumes negative controls are perfect. Since Appendix A.6 admits semantic-negative generation fails for broad concepts, a low causal score may reflect failed controls rather than true false positives. The conclusion is not fully supported without validating control quality.
- **[science]** The statistical test in Appendix A.7 compares target scores against baselines on the *same* region selected to maximize the target score. This circular logic inflates significance. The p-value does not prove causal specificity independent of selection bias, undermining the claim of rigorous validation.

Overreach

Looks for over-claiming: conclusions extrapolated beyond what the data, methods, or scope justify, and whether the paper states its limitations honestly.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_overreach.md

The paper makes several strong claims regarding the prevalence of false positives in activation-based methods and the superior ability of BrainCause to recover “true” representations. While the internal logic of the BrainCause framework is sound and the comparison with MindSimulator is well-executed, the manuscript occasionally overreaches in generalizing these findings to the broader field of neuroscience.

Specifically, the Abstract and Introduction state that “over 70% of localizations would be false positives” and that “a large fraction of localizations would be false positives” without causal validation. The data supporting this (Section 3.1, Fig. 3) shows that 73.4% of the regions *discovered by the MindSimulator baseline* fail the causal test. This is a valid finding about the MindSimulator method and the specific 260 concepts tested. However, extrapolating this to imply that 70% of *all* activation-based discoveries in the literature are false positives is an

overreach. The MindSimulator baseline may have specific failure modes (e.g., reliance on CLIP retrieval) that do not generalize to all activation-maximization approaches used in the field. The language should be tempered to reflect that this high false-positive rate was observed specifically for the baseline method and concept set evaluated, rather than as a universal statistic for the field.

Additionally, the claim that BrainCause “successfully recovers known functional localizations” (Abstract) is slightly overstated given the evidence. Table 1 shows high alignment for broad categories (e.g., 90% of top voxels for “Faces” fall in face-selective regions). However, this does not necessarily demonstrate the recovery of specific, fine-grained functional maps (e.g., distinguishing FFA from OFA with high precision) better than baselines, but rather that the method finds *some* voxels in the correct general vicinity. The paper would benefit from clarifying that it recovers *broad* functional regions consistent with known anatomy, rather than implying a precise recovery of established fine-grained maps that might be difficult to validate without ground-truth anatomical data.

Finally, the conclusion asserts that the work “reveals that many previously identified representations may be driven by correlated factors.” While the paper demonstrates this for the specific concepts and baselines tested, it does not provide a systematic re-analysis of previously published “known” representations (e.g., from the original Kanwisher or Epstein papers) to confirm they are false positives. The claim remains a strong inference based on the current study’s limitations rather than a direct refutation of prior literature. Restricting these claims to the scope of the evaluated methods and datasets would improve the scientific rigor of the manuscript.

Action items.

- **[writing]** The claim that ‘over 70% of localizations would be false positives’ (Abstract) overgeneralizes. The 73.4% figure (Sec 3.1) applies only to regions found by the MindSimulator baseline, not all activation-based methods in the field. Qualify this claim to reflect the specific baseline comparison.
- **[writing]** The Abstract claims BrainCause ‘successfully recovers known functional localizations.’ Table 1 shows alignment with broad categories (e.g., ‘Faces’), but does not demonstrate recovery of specific fine-grained sub-regions (e.g., FFA vs. OFA) with higher fidelity than baselines. Temper the claim to ‘broad functional regions’.
- **[writing]** The conclusion states ‘without causal validation, a large fraction of localizations would be false positives.’ This generalizes beyond the study’s scope (NSD, 260 concepts, specific baselines). Restrict the claim to the evaluated methods and datasets to avoid overreach regarding the broader literature.

Safety Ethics

Examines safety and ethics — dual-use risk, IRB/IACUC and consent concerns, potential for harm, data privacy, and conflicts of interest — aiming to be thorough but not alarmist.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_safety_ethics.md

The paper addresses a significant methodological gap in neuroscience by moving from correlational activation maps to causal validation of visual concept representations. From a safety and ethics perspective, the work is generally sound but requires specific clarifications regarding data provenance and the implications of generative AI in experimental design.

First, regarding human subjects research, the study utilizes the Natural Scenes Dataset (NSD) (Section 4, line 1). While NSD is a public resource, the manuscript must explicitly confirm that the original data collection was approved by an Institutional Review Board (IRB) and that the subjects provided informed consent that covers secondary computational analyses of this nature. Although the authors are not the original data collectors, standard ethical review for secondary analysis requires a statement confirming that the use of the data falls within the scope of the original consent and that no new human subjects were recruited for this specific computational study. This should be added to the “Brain Data” section (Appendix A.1) or the Acknowledgments.

Second, the methodology relies heavily on generative AI (FLUX.2) to synthesize “counterfactual negative images” (Section 3.1). This involves editing images to remove or replace human features (e.g., replacing a human face with an animal face). While the intent is scientific control, the use of generative models to alter human imagery carries inherent risks of creating deepfakes or misleading content. The authors should briefly describe any safety filters or content moderation steps applied to the generated stimuli to ensure they do not violate safety policies (e.g., generating non-consensual sexual imagery, hate speech, or realistic deepfakes of real individuals). A sentence in Section 3.1 or the Appendix regarding the safety protocols for the generative pipeline would be appropriate.

Finally, the paper introduces a method to causally link specific visual concepts to brain regions. While the current application is benign, the capability to precisely map and potentially manipulate or predict brain responses to specific concepts has dual-use potential regarding neuro-privacy and cognitive liberty. The conclusion (Section 6) briefly mentions limitations but does not address the broader ethical implications of such causal mapping. A short paragraph discussing the responsible use of this technology, particularly concerning data privacy and the potential for misuse in understanding or influencing human cognition, would strengthen the ethical standing of the work.

No fatal safety issues were identified, as the study does not involve direct intervention on human subjects or the release of sensitive personal data. However, the clarifications above are necessary to fully satisfy ethical review standards for computational neuroscience involving human data and generative AI.

Action items.

- **[writing]** The manuscript relies on fMRI data from the Natural Scenes Dataset (NSD) involving human subjects. While the data is public, the paper must explicitly state that the original NSD study obtained IRB approval and informed consent, and confirm that this secondary analysis adheres to the original consent scope regarding computational modeling.

- **[writing]** The framework uses generative AI (FLUX.2) to create counterfactual stimuli, including edits that remove human features (e.g., faces, hands). The authors should briefly address potential safety risks regarding the generation of misleading or harmful synthetic imagery and confirm that the generated stimuli were filtered to prevent the creation of prohibited content (e.g., deepfakes, hate speech).
- **[writing]** The paper proposes a framework that could be used to map specific cognitive or visual concepts to brain regions. While currently for research, this capability has potential dual-use implications for neuro-privacy or targeted manipulation. A brief discussion on the ethical boundaries of such causal mapping and data privacy safeguards is recommended.

Scientific Evidence

Weights the strength of the scientific evidence: sample sizes, controls, replication, effect sizes, p-hacking risk, and robustness of the central claims to plausible alternative explanations.

Reviewer model: `qwen.qwen3.5-122b`

Prompt: `agents/prompts/paper_reviewer_scientific_evidence.md`

The paper presents a compelling methodological shift from activation maximization to causal testing for visual concept discovery in fMRI. The sample size (4 subjects from NSD, ~10k images each) is robust, and the use of held-out generated data for validation is a strong design choice. However, the strength of the scientific evidence is currently limited by the reliance on generative models to define the “ground truth” of the counterfactuals.

The central claim—that 70% of activation-based discoveries are false positives (Section 1, line 45)—is derived from the observation that these regions fail to show a positive causal score on generated semantic negatives. While the logic is sound, the evidence is only as strong as the generated negatives. The authors acknowledge in Appendix S.5.4 that semantic-negative generation fails for broad concepts (e.g., “sky”, “reflection”), where the generated “negative” still contains the target. If the “hardest negative” used to calculate the causal score (Section 3.2) is actually a positive image due to generation failure, the causal score will be artificially low, potentially misclassifying a true positive as a false positive. The manuscript needs a quantitative analysis of how generation failure rates correlate with the reported false positive rates to ensure the 70% figure is not an artifact of the generative model’s limitations.

Furthermore, the statistical testing in Appendix S.5.5 compares the target concept score against a baseline of “other concepts” on the same region. This demonstrates selectivity relative to the tested set but does not fully rule out that the region is responding to a confounding low-level feature shared by the target and the baseline. A more rigorous null model, such as comparing against shuffled concept labels or a set of random noise concepts, would strengthen the claim that the discovered regions are truly concept-specific rather than just “different from the other 259 concepts.”

Finally, the effect sizes reported in Table 1 are substantial, but the variance across subjects (Table S.4) shows some inconsistency. While the trend is consistent, a formal interaction test or confidence intervals on the mean differences would provide stronger evidence for the robustness

of the causal advantage across the population.

Action items.

- **[science]** Clarify that the ‘70% false positive’ claim (Sec 1) reflects failure against *generated* alternatives, not ground-truth biological false positives, to avoid overclaiming about prior literature validity.
- **[science]** The statistical test in Appx S.5.5 compares target vs. other concepts on the same region. Add a null distribution test (e.g., shuffled labels) to rigorously rule out noise or random concept responses as the driver of specificity.
- **[science]** Quantify how semantic-negative generation failures (Appx S.5.4) impact the reported false positive rate. If ‘hardest negatives’ are actually positives due to generation errors, causal scores are biased; a sensitivity analysis is required.

Statistical Analysis

Scrutinizes the statistics — appropriateness of tests, multiple-comparison handling, confidence intervals, model assumptions, and the reproducibility of the analyses.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_statistical_analysis.md

The statistical analysis framework in BrainCause introduces a novel causal scoring mechanism, but the manuscript lacks rigorous validation of significance and false discovery rate control.

First, the empirical p-value calculation in Appendix A (Section **sec_sup:statistical_test**) compares target scores against an LLM-defined baseline of “distinct concepts” rather than a null distribution (e.g., shuffled labels). This introduces dependency on the semantic similarity of the baseline set, which is unquantified. More critically, the authors test 260 concepts across 4 subjects (1,040 tests) but report no correction for multiple comparisons (e.g., Benjamini-Hochberg FDR). Given the central claim that activation-based methods have a ~70% false positive rate, the absence of FDR control on the proposed method’s discoveries is a significant omission.

Second, quantitative results in Table 1 (**tab:quant_main**) and ablation tables (e.g., **tab_sup:Abaltion_scores**) report mean scores across concepts and subjects but omit measures of variability (standard deviation, standard error, or confidence intervals). The reported improvements (e.g., BrainCause causal score of 0.62 vs. MindSimulator’s -0.44) appear substantial, but without error bars or reported statistical tests (e.g., paired t-test) comparing methods across the 50 concepts, the statistical significance of these differences remains unverified. The text mentions “statistical tests” in Section 3.3 but does not detail test statistics or p-values for the method comparisons.

Finally, the voxel selection criterion in Section 3.2 and Appendix A.4 relies on a deterministic threshold ($S_{causal}(v) > 0$) on a difference score derived from noisy fMRI predictions. The authors do not address the multiple testing problem inherent in selecting from ~40,000 voxels per subject. Without a permutation-based null distribution for voxel-wise scores or an FDR correction applied to the selection process, the reported “false positive” reduction may be an artifact

of the thresholding method rather than a true causal effect. The authors should provide a permutation analysis to establish the null distribution of the causal score and apply appropriate multiple-comparison corrections.

Action items.

- **[science]** The empirical p-value method in Appendix A uses LLM-selected baselines rather than a null distribution. Clarify if this controls for confounds. Crucially, no multiple-comparison correction (e.g., FDR) is reported for the 260 concepts tested, which is vital given the claimed 70% false positive rate in baselines.
- **[science]** Table 1 and ablation tables report mean scores without variance (SD/SE) or confidence intervals. Without error bars or statistical tests (e.g., paired t-tests) comparing methods across the 50 concepts, the significance of reported improvements (e.g., 0.62 vs -0.44) cannot be rigorously assessed.
- **[science]** The voxel selection threshold ($S_{\text{causal}} > 0$) in Sec 3.2 ignores the multiple testing problem across ~40k voxels. A permutation test or FDR control for voxel-wise selection is required to validate the reported false positive reduction and ensure the threshold is not arbitrary.

Writing Quality

Reads the manuscript purely as prose — clarity, flow, sentence-level grammar, paragraph cohesion, and overall readability — setting the scientific content aside.

Reviewer model: qwen.qwen3.5-122b

Prompt: agents/prompts/paper_reviewer_writing_quality.md

The manuscript is generally well-written, with clear and logical flow in the introduction and methodology sections. The argument for moving from activation-based to causal-based discovery is articulated effectively. However, there are several specific typos and inconsistencies that require correction to ensure professional polish.

First, there are noticeable typos in figure labels and section references. In Section 3.1, the caption for Figure 2 refers to “Casulity” (line 234 in the provided source), which should be “Causality”. Similarly, in the Appendix, the table label for the ablation study is misspelled as `tab_sup:Abaltion_scores` (line 1024), and the reference to the subject alignment section in the main text contains a typo: `sbuecjts` instead of `subjects` (line 338). These errors, while minor, detract from the overall quality of the presentation.

Second, there is a slight inconsistency in the naming of the baseline method. The text in Section 3.1 refers to “MindSimulator+VLM” (line 285), while the corresponding row in Table 1 (line 306) and the description in the Appendix (line 1056) use “MindSimulator+”. The authors should standardize this nomenclature throughout the paper to avoid confusion.

Finally, in Section 2, the phrase “image-fMRI” is used frequently. While the double hyphen is correct for an en-dash in LaTeX, the spacing around it in some instances (e.g., “image-fMRI dataset”) feels slightly inconsistent with standard typesetting practices where a non-breaking

space might be preferred, though this is a minor stylistic point. The primary focus for revision should be on correcting the explicit typos identified above.

Action items.

- **[writing]** In Section 3.1, the caption for Figure 2 contains a typo: ‘Casulity’ should be corrected to ‘Causality’ in the label ‘fig:Good_and_bad_Casulity_Edits’ and the caption text.
- **[writing]** In Appendix A.5, the table label ‘tab_sup:Abaltion_scores’ contains a typo (‘Abaltion’ instead of ‘Ablation’). Additionally, the main text reference in Section 4.3 to ‘Appendix~\ref{sec_sup:Quantitative_across_sbuecjts}’ contains a typo (‘sbuecjts’ instead of ‘subjects’).
- **[writing]** In Section 3.1, the phrase ‘MindSimulator+VLM’ is used, but the table in the same section lists the method as ‘MindSimulator+’. Ensure consistent naming throughout the text and tables to avoid reader confusion.
